(February 1, 2008)

Quasiparticle transport in the vortex state of an s -wave superconductor at $T \rightarrow 0$ was investigated by measuring the thermal conductivity of $\text{LuNi}_2\text{B}_2\text{C}$ down to 70 mK in a magnetic field perpendicular to the heat current. In zero field, there is no electronic conduction, as expected for a superconducting gap without nodes. However, as soon as vortices enter the sample quasiparticles are seen to conduct remarkably well, even better than they would in a typical d -wave superconductor. This is in stark conflict with the widely held view that quasiparticle states in s -wave superconductors just above H_{c1} should be localized and bound to the vortex core.

PACS numbers: 74.70.Tx, 74.25.Fy

The physics of weakly interacting electrons in non-magnetic weakly disordered metals and superconductors with three-dimensional crystal structures is thought to be extremely well understood, in the following limits: the s -wave superconductor in zero magnetic field and the metallic state at low temperature. The former is described by the theory of Bardeen, Cooper and Schrieffer (BCS) and the latter by the Fermi-liquid theory of Landau, two cornerstones of solid state theory. These two limits can be achieved in the same material and the electron system can be made to go smoothly from one to the other simply by applying a magnetic field H , going from zero to above H_{c2} , the upper critical field beyond which superconductivity is destroyed.

The s -wave superconductor at $T \rightarrow 0$ and $H = 0$ is a thermal insulator, in that the electron system cannot transport any heat: the Cooper pairs carry no entropy and there are no quasiparticles. On the other hand, the normal state above H_{c2} is a thermal metal. The two states may be characterized by their heat conductivity $\kappa(T)$, through the value of the residual linear term κ_0/T , defined as the limit of κ/T when $T \rightarrow 0$. κ_0/T is zero in the s -wave superconductor and finite in the metal, where it is given precisely by the Wiedemann-Franz law. This law is a universal relation between charge conductivity and heat conductivity at $T \rightarrow 0$, given by $\kappa_0/T = L_0/\rho_0$, where ρ_0 is the residual electrical resistivity.

A basic question arises: how does the electron system evolve between these two well-defined and well-understood limits, these two distinct states of matter? Remarkably, this question is still largely unanswered.

In superconductors of the second kind (type II), the electron system responds to an applied magnetic field greater than a critical value H_{c1} by generating vortices, *i.e.* lines of quantized flux at the core of which the

superconducting gap goes to zero. Our basic question then becomes: what is the nature of the electronic states as a function of vortex density? The density is given strictly by the magnetic field strength B as Φ_0/B , where $\Phi_0 = hc/2e$ is the quantum of flux. Considerable progress has been made over the past decade in elucidating the extreme limits of very low density and very high density. A single isolated vortex in an s -wave superconductor with an isotropic zero-field gap Δ_0 introduces a discrete set of energy levels inside the vortex core, the lowest level lying an energy $\Delta_0/2k_F\xi$ above the Fermi energy, with higher levels spaced equally by twice that amount [1], where k_F is the Fermi wavevector and ξ is the vortex core radius. The density of states associated with these levels is roughly that of the normal state, but limited to an area $\pi\xi^2$, where ξ is of order 100-1000 Å in most s -wave superconductors. The important point is that the states associated with a single vortex are not extended but localized, bound to the vortex core. The detailed variation of the local density of states associated with a vortex was mapped out using STM on NbSe_2 by Hess *et al.* [2] and interpreted in terms of states bound to the vortex core [3]. In the presence of a vortex lattice, the quasiparticle states form bands [4,5], but at fields low enough that the intervortex separation d is much larger than the vortex core size, the low-lying bands are very flat [5], essentially identical to the localized levels of the isolated vortex (and therefore also gapped). In other words, when the ratio ξ/d is very small, the tunneling between states on neighbouring vortices is exponentially small, causing very little dispersion.

In the other limit of fields close to H_{c2} , quasiparticles are delocalized, as inferred for example from the observation of de Haas-van Alphen oscillations in type-II superconductors such as NbSe_2 [6], V_3Si [7] and $\text{YNi}_2\text{B}_2\text{C}$

[8]. In this limit, calculated bands are broadened Landau levels with zero-energy quasiparticles occurring at several k points in the magnetic Brillouin zone [4]. Tešanović and Sacramento have argued that the high-field gapless phase is separated from the low-field gapped phase by a quantum level crossing transition [9].

The picture for very low and very high vortex densities is therefore expected to be much the same as at $H = 0$ and $H = H_{c2}$, namely that of localized vs delocalized quasiparticles, respectively. The best way to investigate the nature of quasiparticle states and the possibility of a metal-insulator transition is to measure heat transport. Note that charge transport is much less ideal, either theoretically since charge is not a conserved quantity, or experimentally since charge dynamics is dominated by the dissipation caused by moving vortices (flux flow regime). In this Letter, we report on the first systematic study of heat transport throughout the vortex state of an s -wave superconductor. Contrary to all expectations, we observe highly delocalized quasiparticles at temperatures as low as $T_c/200$ for all values of the field in the vortex state. There is no indication of an insulator-to-metal transition between H_{c1} and H_{c2} , even though the ratio d/ξ starts off as large as 10-20 at H_{c1} .

The borocarbide material $\text{LuNi}_2\text{B}_2\text{C}$ was chosen because of its large critical field ratio $H_{c2}/H_{c1} \simeq 100$, which allows access to a wide range of intervortex separations. It is a non-magnetic superconductor thought to be characterized by s -wave pairing and a gap without nodes. Its crystal structure is tetragonal and its Fermi surface properties nearly isotropic. The thermal conductivity was measured in a dilution refrigerator using a standard steady-state technique. The temperature was swept at fixed magnetic fields, from 70 mK up, in fields ranging from 0 to 8 T. The field was applied perpendicular to the heat current and parallel to the c -axis ([001] direction). Below 1.5 T, the sample was cooled in the field to ensure a good field homogeneity and a well-ordered vortex lattice. Above 1.5 T, the results were independent of cooling procedure. The single crystal was grown by a melting flux method described elsewhere [10]. The sample was shaped and polished into a rectangular parallelepiped of width 0.495 mm (along [010]) and thickness 0.233 mm (along [001]), with a 1.59 mm separation between contacts (along [100]). The same contacts were used for electrical resistivity and thermal conductivity measurements, made with non-superconducting solder and yielding contact resistances lower than 5 m Ω at 300 K. In zero magnetic field, the resistivity was $\rho(300 \text{ K}) = 35 \mu\Omega \text{ cm}$ at room temperature and $\rho_0 = 1.30 \mu\Omega \text{ cm}$ at $T \rightarrow 0$, using an extrapolation of the form $\rho = \rho_0 + AT^2$ between T_c and 50 K, yielding an RRR of 27. T_c was found to be 16 K with a transition width of 1 K. Magnetoresistive measurements performed at 1.8 K yielded $H_{c2} = 7 \text{ T}$ and $\rho = 1.67 \mu\Omega \text{ cm}$ just above H_{c2} . The zero-temperature coherence length $\xi_0 = 70 \text{ \AA}$, using $H_{c2}(0) = \Phi_0/2\pi\xi_0^2$.

FIG. 1. Thermal conductivity of $\text{LuNi}_2\text{B}_2\text{C}$ between 2.5 and 25 K. The superconducting transition occurs at $T_c = 16 \text{ K}$ and can be seen as a kink in the thermal conductivity. The large peak centered at 5 K is due to a rapid increase in the phonon mean free path as the electrons condense below T_c . *Inset*: Thermal conductivity at $T = 2.1 \text{ K}$ as a function of magnetic field. The downward deviation from a constant conductivity at a field $H_{c1} \simeq 60 \text{ mT}$ signals the onset of vortex entry into the sample.

Note that the radius of the vortex cores are somewhat larger than this at low fields (by a factor 2 or so) as measured by muon spin rotation (μSR) in this compound [11]. A similar expansion was previously reported in NbSe_2 [12].

The thermal conductivity of $\text{LuNi}_2\text{B}_2\text{C}$ in zero magnetic field is plotted in Fig. 1 as $\kappa(T)$ vs T up to T_c and beyond. The total conductivity is the sum of an electronic and a phononic contribution: $\kappa = \kappa_e + \kappa_{ph}$. Above T_c , κ is dominated by electrons, as κ_{ph} is severely limited by electron scattering. As the temperature is decreased below T_c , two things happen as electrons condense into Cooper pairs: κ_e decreases as there are fewer and fewer thermally excited quasiparticles and κ_{ph} increases as fewer unpaired electrons are available to scatter phonons. The first effect is seen as a dip right at T_c and the latter leads to a huge increase in phonon mean free path giving rise to the pronounced peak at 5 K. This increase is expected to stop when the number of thermally excited quasiparticles becomes vanishingly small. In a typical BCS superconductor such as Nb, the peak occurs roughly at $T_c/5$, the temperature at which κ_e becomes negligible (less than 1-2% of its normal state value). The fact that in $\text{LuNi}_2\text{B}_2\text{C}$ the peak is even higher in temperature is an indication that there are very few quasiparticles below $T_c/3$, which tends to

confirm the *s*-wave nature of the gap and rule out any sizable gap anisotropy. At temperatures below $T_c/3$, κ is essentially all due to phonons, whose mean free path eventually grows to reach the size of the crystal, at which point a cubic temperature dependence is observed. This is shown in Fig. 2, in a plot of κ/T vs T^2 , which allows us to easily separate the electronic term linear in T from the phononic term cubic in T . The zero-field curve is indeed linear in such a plot (below 150 mK), with zero intercept and a slope in quantitative agreement with the known sound velocities and sample dimensions, as reported earlier [13]. The absence of any residual linear term is a second confirmation that there are no nodes in the gap (at least in the basal plane). To be more specific, the data sets an upper limit of $\kappa_0/T \simeq 0.01 \text{ mW K}^{-2} \text{ cm}^{-1} \simeq (\kappa_N/T)(1/2000)$ on a possible residual linear term arising from nodes in the basal plane. Theoretically, the value expected from a line node in the basal plane is roughly $\kappa_0/T \simeq (\kappa_N/T)(\hbar\Gamma/2\Delta_0)$, where $\Gamma = 1/2\tau_N$ is the impurity scattering rate and Δ_0 is the gap maximum [14]. We can estimate τ_N , the transport relaxation time in the normal state, from kinetic theory: $\kappa_N/T = L_0/\rho_0 = \frac{1}{3}\gamma_N v_F^2 \tau_N$, where γ_N is the Sommerfeld coefficient of the specific heat and v_F is the Fermi velocity. The measured values are $\gamma_N = 19.5 \text{ mJ K}^{-2} \text{ mole}^{-1}$ [15], $\Delta_0 = 3.2 k_B T_c$ [16] and $v_F \simeq 2 \times 10^5 \text{ m/s}$ [17]. These numbers give a mean free path $l_N = v_F \tau \simeq 500 \text{ \AA}$, and $\hbar\Gamma \simeq 0.5\Delta_0$, from which we would expect $\kappa_0/T \simeq \frac{1}{4}\kappa_N/T$ if there were nodes in the gap. This huge discrepancy, by a factor of nearly three orders of magnitude, argues strongly against nodes in the gap function of $\text{LuNi}_2\text{B}_2\text{C}$ (and the insensitivity to impurities argues against an unconventional order parameter).

As seen in Fig. 2, a residual linear term is induced by a magnetic field applied perpendicular to the heat current. When the field exceeds $H_{c2}(0) = 7 \text{ T}$, the conductivity is dominated by electrons and $\kappa/T \simeq \kappa_e/T$ is essentially constant, as seen for 8 T, with a value in perfect agreement with the Wiedemann-Franz law: $\kappa_e/T = L_0/\rho$, where $\rho = \rho(8 \text{ T})$. Turning to very low fields, we use the fact that phonons are scattered by vortices to determine *in situ* the field H_{c1} at which vortices first enter the sample. This is shown in the inset of Fig. 1, where κ_{ph} at $T = 2.1 \text{ K}$ is seen to suddenly deviate from its field-independent value at $H_{c1} \simeq 60 \text{ mT}$. Note that at 60 mT, it is known from small-angle neutron scattering [18] that vortices form a well-ordered square lattice in $\text{LuNi}_2\text{B}_2\text{C}$. The question of fundamental interest is: how is the electronic conduction modified by the presence of a vortex lattice? The low field behavior is shown in the lower panel of Fig. 2. The curves of κ/T vs T^2 for fixed fields of 50, 75, 100, 200 and 300 mT are seen to be rigidly shifted relative to the zero field curve. The growth of the corresponding residual linear term, which is the electronic contribution, is plotted in Fig. 3. The striking

FIG. 2. Temperature dependence of the thermal conductivity at several applied fields in the range $70 \text{ mK} < T < 300 \text{ mK}$. The data is plotted as κ/T vs T^2 to separate the electronic and phononic contributions. Fig 1 (a) shows the data for $H = 0, 0.3, 1.5, 4, 6$ and 8 T , in increasing order. The solid line indicates the value expected from the Wiedemann-Franz law above H_{c2} . Fig. 1 (b) shows the data for $H = 0, 50, 75, 100, 200$ and 300 mT , in increasing order. At low fields, the phononic term remains largely unchanged as the electronic term grows with increasing field.

feature is that this growth starts right at H_{c1} , as can be seen from the inset. Whereas quasiparticles in an *s*-wave superconductor close to H_{c1} are theoretically expected to be localized and thus incapable of transporting heat at $T \rightarrow 0$, the observed quasiparticle conduction is excellent. $\text{LuNi}_2\text{B}_2\text{C}$ is therefore a thermal metal (with fully delocalized quasiparticles) throughout the vortex state, at least down to $T_c/200$. This provides a natural explanation for the fact that de Haas-van Alphen oscillations in $\text{YNi}_2\text{B}_2\text{C}$ persist down to unusually low fields ($H_{c2}/5$) [8] and no localized core states have been detected in STM spectroscopy on borocarbide superconductors.

The growth of quasiparticle conduction with field is remarkably fast. At low fields, it is linear in field (see inset of Fig. 3) and given by

$$\frac{\kappa_0}{T} \simeq \frac{L_0}{\rho_0} \frac{H - H_{c1}}{H_{c2}} \quad , \quad (1)$$

where ρ_0 is the zero-field normal-state resistivity. In

some sense, this suggests that a quasiparticle in the vortex state conducts heat just as well as in the normal state (where $\frac{\kappa_0}{T} = \frac{L_0}{\rho_0}$), if the density of quasiparticles is assumed to grow roughly as B/H_{c2} .

It is striking to note that quasiparticles in this s -wave superconductor conduct better than they do in a typical d -wave superconductor. Indeed, from calculations by Vekhter and Houghton [19],

$$\frac{\kappa_0}{T} < \frac{\kappa_N}{T} \frac{H}{H_{c2}} \quad , \quad (2)$$

for all H in the vortex state of a d -wave superconductor. Note however that the H dependence is different: it is sublinear for d -wave at low H , largely due to the $\sqrt{H}$ dependence of the density of states, whereas we find a linear dependence at the lowest fields, perhaps even going to super linear (see Fig. 3).

In trying to explain the surprisingly good conduction, it is natural to invoke a highly anisotropic gap function, and ascribe the excellent heat transport to the field-induced excitation of quasiparticles across a very small gap in the basal plane. Izawa *et al.* have recently interpreted the $\sqrt{H}$ dependence of the specific heat in $\text{YNi}_2\text{B}_2\text{C}$ [20] in terms of a Doppler shift of the quasiparticle spectrum akin to what is seen in d -wave superconductors [19,21] but applied in this case to a highly anisotropic s -wave gap, with a small minimum gap $\Delta_{\min}$. This scenario is unsatisfactory in several respects. First, it requires a huge gap anisotropy in a Fermi liquid that is otherwise rather isotropic. Indeed, because quasiparticle conduction starts right at H_{c1} , the average Doppler shift energy $E_H \simeq \Delta_0 \sqrt{H/H_{c2}}$ [21] at H_{c1} must be greater than the minimum gap:

$$\Delta_{\min} < E_H(H_{c1}) \simeq \Delta_0 \sqrt{H_{c1}/H_{c2}} = \Delta_0/10 \quad . \quad (3)$$

This factor of 10 or more in gap anisotropy should be compared to the very small mass tensor anisotropy (*e.g.* from H_{c2}), equal to 1.01 in $\text{YNi}_2\text{B}_2\text{C}$ and 1.16 in $\text{LuNi}_2\text{B}_2\text{C}$ [17]. Secondly, as mentioned above, it is hard to see how phonon conductivity could rise to a huge peak at 5 K if there was significant thermal excitation of quasiparticles for $T < 5$ K, as there would be with $\Delta_{\min} \simeq 1$ K. The third problem is that we observe the same excellent quasiparticle transport at very low fields in a crystal of $\text{LuNi}_2\text{B}_2\text{C}$ doped with 9% Co impurities. The doping causes the scattering rate to be 7 times larger than in the pure crystal, so that $\hbar\Gamma \simeq 3.5\Delta_0$ and $l_N \simeq \xi$. Such strong impurity scattering should essentially wipe out all anisotropy in the gap function [22], yet we observe the same transport behaviour in the vortex state of both pure and impure samples.

This last fact also argues against the speculation by Nohara *et al.* [23] that the field dependence of the specific heat in $\text{YNi}_2\text{B}_2\text{C}$ goes from $\gamma(H) \sim \sqrt{H}$ to linear in H upon doping with 20% Pt because quasiparticles go

FIG. 3. Magnetic field dependence of the electronic thermal conductivity κ/T at $T \rightarrow 0$. The current is along the a -axis [100] of the crystal and perpendicular to the applied field. The arrow gives the value of H_{c2} obtained from resistivity. Note the rapid rise in κ/T and the saturation above H_{c2} at a value exactly given by the Wiedemann-Franz law. Inset: zoom at low fields, where a linear growth is seen to extrapolate precisely at the independently measured H_{c1} .

from being delocalized (coherent hopping between adjacent vortices) to being localized (incoherent hopping). We are therefore led to regard the presence of delocalized quasiparticles as a property of the vortex lattice state and not as the result of nodes or deep minima in the gap function. To the best of our knowledge, a proper calculation of the thermal conductivity in the vortex lattice state of an s -wave superconductor at low fields has never been reported. It would have to start from the quasiparticle band structure of the vortex lattice, such as calculated by Yasui and Kita [5]. For an isotropic s -wave gap and a hexagonal vortex lattice at $B = 0.1H_{c2}$, these authors find the two lowest energy bands to be at an energy of $\Delta_1 \simeq \Delta_0/2k_F\xi$ above E_F and have very low dispersion, with a band velocity no greater than $v \simeq (a\Delta_0/\hbar\pi)/100$. These two factors conspire to reduce the expected heat conduction relative to the normal state very considerably, and it may be difficult to reconcile our results with such an energy spectrum. First, the existence of a (mini)gap Δ_1 should give rise to an exponential decrease of κ/T with temperature for $k_B T < \Delta_1$. A rough estimate gives $\Delta_1 \simeq 300$ mK, using $k_F \simeq \pi/2a$ and $\xi \simeq 100$ Å, yet we observe no decrease down to 70 mK.

Even if we assume that the lowest bands are somehow thermally populated, it is still difficult to see how they could lead to such excellent conduction, given how flat they are. Conductivity is weighted by the square of the carrier velocity, or band dispersion, which alone should

suppress κ/T by a factor $(v/v_F)^2$ relative to the normal state. This implies a reduction by a factor 2×10^7 at $B = 0.1H_{c2}$. At that field, κ_e is only down by a factor 10. It remains to be calculated whether the transport relaxation time τ in the vortex state is sufficiently enhanced to compensate for that factor of 10^6 .

Theoretical expectations of a quantum phase transition from thermal metal to thermal insulator as the vortex separation is increased by going to lower fields are not confirmed in our experiments. The appearance of a gap at a quantum level crossing transition, proposed by Tešanović and Sacramento [9], could conceivably have been missed if one postulates that the minigap is in fact smaller than our estimate of $\Delta_1 \simeq 300$ mK, by a factor of 4 (or more). The localization of quasiparticles as a result of disorder, discussed by Vishveshwara *et al.* [24], may simply not occur in the samples we studied (both pure and Co-doped) because the level of disorder is not high enough.

In summary, highly delocalized quasiparticles are present in $\text{LuNi}_2\text{B}_2\text{C}$ in magnetic fields as low as H_{c1} , in sharp contrast with the standard picture of quasiparticle states bound to the vortex cores at very low fields. We believe that this remarkably good quasiparticle conduction is an intrinsic property of the vortex lattice state as opposed to being caused by a hugely reduced gap in the basal plane. Calculations of heat transport in the vortex lattice state are needed to explore the apparent compensation between the very low band dispersion (or quasiparticle velocity) and the transport relaxation time. Measurements on other superconductors are necessary in order to determine whether our findings are peculiar to borocarbides or a more generic property of *s*-wave superconductors.

We are grateful to Z. Tešanović, S. Vishveshwara, T. Senthil, M.P.A. Fisher and Michael Walker for stimulating discussions.
